Implementation of Optimized DES Encryption Algorithm upto 4 Round on Spartan 3

Nimmi Gupta

Abstract— **Data Security is an important parameter for the industries. It can be achieved by Encryption algorithms which are used to prevent unauthorized access of data. Cryptography is the science of keeping data transfer secure, so that eavesdroppers (or attackers) cannot decipher the transmitted message. In this paper the DES algorithm is optimized upto 4 round using Xilinx software and implemented on Spartan 3 Modelsim. The paper deals with various parameters such as variable key length, key generation mechanism, etc. used in order to provide optimized results.**

Index Terms— **Encryption, Hacker, Key, S-boxes, Modelsim.**

I. INTRODUCTION

Cryptography includes two basic components: Encryption algorithm and Keys. If sender and recipient use the same key then it is known as symmetrical or private key cryptography. It is always suitable for long data streams. Such system is difficult to use in practice because the sender and receiver must know the key. It also requires sending the keys over a secure channel from sender to recipient [4]. The question is that if secure channel already exist then transmit the data over the same channel. On the other hand, if different keys are used by sender and recipient then it is known as asymmetrical or public key cryptography. The key used for encryption is called the public key and the key used for decryption is called the private key. Such technique is used for short data streams and also requires more time to encrypt the data [3]. To encrypt a message, a public key can be used by anyone, but the owner having private key can only decrypt it. There is no need for a secure communication channel for the transmission of the encryption key. Asymmetric algorithms are slower than symmetric algorithms and asymmetric algorithms cannot be applied to variable-length streams of data. Section 1 includes the introduction of cryptography. Section 2 describes the cryptography techniques. Section 3 includes the analysis and implementation of DES Algorithm using Xilinx software. Conclusion has been included in Section 4.

II. CRYPTOGRAPHY TECHNIQUES

There are two techniques used for data encryption and decryption, which are:

2.1 Symmetric Cryptography

If sender and recipient use the same key then it is known as symmetrical or private key cryptography. It is always suitable for long data streams. Such system is difficult to use in practice because the sender and receiver must know the key. It also requires sending the keys over a secure channel from sender to recipient. There are two methods that are used in symmetric key cryptography: block and stream.

The block method divides a large data set into blocks (based on predefined size or the key size), encrypts each block separately and finally combines blocks to produce encrypted data.

The stream method encrypts the data as a stream of bits without separating the data into blocks. The stream of bits from the data is encrypted sequentially using some of the results from the previous bit until all the bits in the data are encrypted as a whole.

2.2 Asymmetric Cryptography

If sender and recipient use different keys then it is known as asymmetrical or public key cryptography. The key used for encryption is called the public key and the key used for decryption is called the private key. Such technique is used for short data streams and also requires more time to encrypt the data. Asymmetric encryption techniques are almost 1000 timess lower than symmetric techniques, because they require more computational processing power. To get the benefits of both methods, a hybrid technique is usually used. In this technique, asymmetric encryption is used to exchange the secret key; symmetric encryption is then used to transfer data between sender and receiver.

III. DES ALGORITHM

Data Encryption Standard (DES) is a cryptographic standard that was proposed as the algorithm for the secure and secret items in 1970 and was adopted as an American federal standard by National Bureau of Standards (NBS) in 1973. DES is a block cipher, which means that during the encryption process, the plaintext is broken into fixed length blocks and each block is encrypted at the same time.

Volume 2, Issue 1

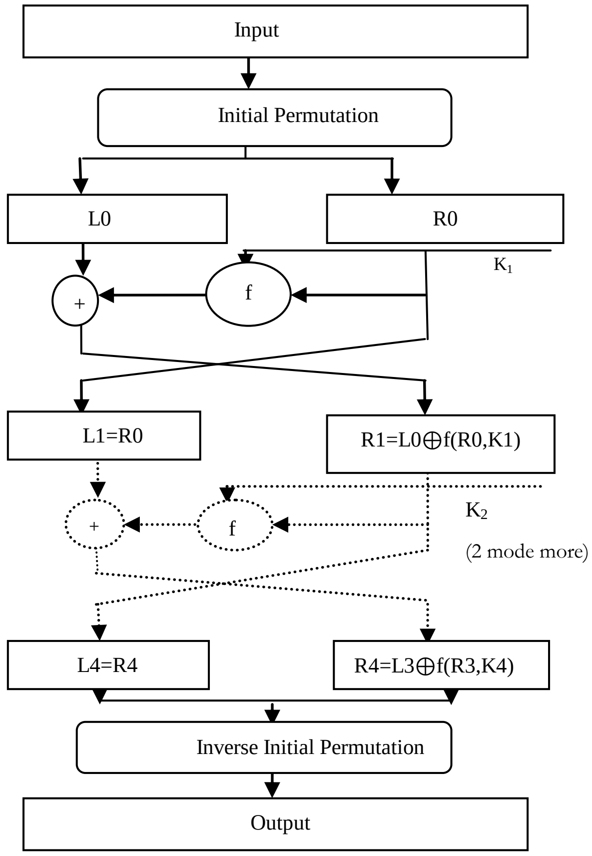

Fig. 1:DES Fiestel Diagram

Basically it takes a 64 bit input plain text and a key of 64-bits (only 56 bits are used for conversion purpose and rest bits are used for parity checking) and produces a 64 bit cipher text by encryption and which can be decrypted again to get the message using the same key. Additionally, we must highlight that there are four standardized modes of operation of DES: ECB (**E**lectronic **C**ode**b**ook mode), CBC (**C**ipher **B**lock **C**haining mode), CFB (**C**ipher **F**eed**b**ack mode) and OFB (**O**utput **F**eed**b**ack mode). The general depiction of DES encryption algorithm which consists of initial permutation of the 64 bit plain text and then goes through 4 rounds, where each round consists permutation and substitution of the text bit and the inputted key bit, and at last goes through a inverse initial permutation to get the 64 bit cipher text

A. Steps of Algorithm:

Create 4 sub-keys, each of which is 48-bits long: The 64-bit key is permuted according to the following table, PC-1. Since the first entry in the table is "57", this means that the 57th bit of the original key K becomes the first bit of the permuted key K+. The 49th bit of the original key becomes the second bit of the permuted key. The 4th bit of the original key is the last bit of the permuted key. Note only 56 bits of the original key appear in the permuted key.

Table 1:
PC-1

PC-1: Permuted Choice 1							
Bit	**0**	**1**	**2**	**3**	**4**	**5**	**6**
1	57	49	41	33	25	17	9
8	1	58	50	42	34	26	18
15	10	2	59	51	43	35	27
22	19	11	3	60	52	44	36
29	63	55	47	39	31	23	15
36	7	62	54	46	38	30	22
43	14	6	61	53	45	37	29
50	21	13	5	28	20	12	4

Example: From the original 64-bit key
K =1111111111111111000000000000000010101010101
010100101010101010101
we get the 56-bit permutation
K_+=00110011110000011001100111100001100111110000
11001100110011
Next, split this key into left and right halves, C0 and D0, where each half has 28 bits.
Example: From the permuted key K+, we get
C_0 = 0011001111000011001100111100
D_0 = 0011001111000011001100110011

With C_0 and D_0 defined, we now create sixteen blocks C_n and D_n, 1<=n<=4. Each pair of blocks C_n and D_n is formed from the previous pair Cn-1 and Dn-1, respectively, for n = 1, 2, … 4, using the schedule of "left shifts" of the previous block. To do a left shift, move each bit one place to the left, except for the first bit, which is cycled to the end of the block. This means, for example, C_3 and D_3 are obtained from C_2 and D_2, respectively, by two left shifts, and C_4 and D_4 are obtained from C_3 and D_3, respectively, by one left shift. In all cases, by a single left shift is meant a rotation of the bits one place to the left, so that after one left shift the bits in the 28 positions are the bits that were previously in positions 2, 3,..., 28, 1.
Example: From original pair C_0 and D_0 we obtain:
C_0 = 0011001111000011001100111100
D_0 = 0011001111000011001100110011
C_1 = 1110000110011001010101011111
D_1 = 0110011110000110011001100110
We now form the keys K_n, for 1<=n<=4, by applying the following permutation table to each of the concatenated pairs C_nD_n. Each pair has 56 bits, but PC-2 only uses 48 of these. Therefore, the first bit of K_n is the 14th bit of C_nD_n, the second bit the 17th, and so on, ending with the 48th bit ofK_n being the 32th bit of C_nD_n. Example: For the first key we have C_1D_1 = 011001111000110 01100111 10000110

Table 2:
PC-2

PC-2: Permuted Choice 2						
Bit	**0**	**1**	**2**	**3**	**4**	**5**

Volume 2 , Issue 1

01111000 01100110 01100110 which, after we apply the permutation PC-2, becomes

K_1=000110110000001011101111111111000111000001110010

Encode each 64-bit block of data: There is an initial permutation IP of the 64 bits of the message data M. This rearranges the bits according to the following table, where the entries in the table show the new arrangement of the bits from their initial order.The 58th bit of M becomes the first bit of IP. The 50th bit of M becomes the second bit of IP. The 7th bit of M is the last bit of IP. Example: Applying the initial permutation to the block of text M, given previously, we get

M=00000001001000110100010101100111100010011010 10 111100110111101111

IP=11001100000000001100110011111111111100001010 10 101111000010101010

Here the 58th bit of M is "1", which becomes the first bit of IP. The 50th bit of M is "1", which becomes the second bit of IP. The 7th bit of M is "0", which becomes the last bit of IP. Next divide the permuted block IP into a left half L_0 of 32 bits, and a right half R_0 of 32 bits.

Example: From IP, we get L_0 and R_0

L_0 = 11001100000000001100110011111111

R_0 = 11110000101010101111000010101010

We now proceed through 4 iterations, for 1<=n<=4, using a function f which operates on two blocks--a data block of 32 bits and a key K_n of 48 bits--to produce a block of 32 bits. Let + denote XOR addition, (bit-by-bit addition modulo 2). Then for n going from 1 to 4 we calculate $L_n = R_{n-1}$ $R_n = L_{n-1} + f(R_{n-1},K_n)$n This results in a final block, for n = 4, of L_4R_4. That is, in each iteration, we take the right 32 bits of the previous result and make them the left 32 bits of the current step. For the right 32 bits in the current step, we XOR the left 32 bits of the previous step with the calculation f . Example: For n = 1, we have

K_1=00011011000000101110111111111110001110000 01110010

$L_1 = R_0$ = 1111 0000 1010 1010 1111 0000 1010 1010

$R_1 = L_0 + f(R_0,K_1)$ It remains to explain how the function f works. To calculate f, we first expand each block R_{n-1} from

Table 3: IP

IP: Initial Permutation								
Bit	**0**	**1**	**2**	**3**	**4**	**5**	**6**	**7**
1	58	50	42	34	26	18	10	2
9	60	52	44	36	28	20	12	4
17	62	54	46	38	30	22	14	6
25	64	56	48	40	32	24	16	8
33	57	49	41	33	25	17	9	1
41	59	51	43	35	27	19	11	3
49	61	53	45	37	29	21	13	5
57	63	55	47	39	31	23	15	7

32 bits to 48 bits. This is done by using a selection table that repeats some of the bits in R_{n-1} We'll call the use of this selection table the function E. Thus $E(R_{n-1})$ has a 32 bit input block, and a 48 bit output block. Thus the first three bits of $E(R_{n-1})$ are the bits in positions 32, 1 and 2 of R_{n-1} while the last 2 bits of $E(R_{n-1})$ are the bits in positions 32 and 1.Example: We calculate $E(R_0)$ from R_0 as follows:

R_0 = 1111 0000101010101111000010101010

$E(R_0)$=011110100001010101010101011110100001010101 010101

(Note that each block of 4 original bits has been expanded to a block of 6 output bits.) Next in the f calculation, we XOR the output E(Rn-1) with the key Kn: Kn + E(Rn-1). Example: For K1 , E(R0), we have

K1=000110110000001011101111111111000111000001 110010

(R0)=011110100001010101010101011110100001010 1 010101

K1+E(R0)=011000010001011110111010100001100110010100 100111

To this point we have expanded Rn-1 from 32 bits to 48 bits, using the selection table, and XORed the result withn the key Kn . We now have 48 bits, or eight groups of six bits. We now do something strange with each group of six bits: we use them as addresses in tables called "S boxes". Each group of six bits will give us an address in a different S box. Located at that address will be a 4 bit number. This 4 bit number will replace the original 6 bits. The net result is that the eight groups of 6 bits are transformed into eight groups of 4 bits (the 4-bit outputs from the S boxes) for 32 bits total. Write the previous result, which is 48 bits, in the form:

Kn + E(Rn-1) =B1B2B3B4B5B6B7B8,

where each B_i is a group of six bits. We now calculate$S_1(B_1)S_2(B_2)S_3(B_3)S_4(B_4)S_5(B_5)S_6(B_6)S_7(B_7)S_8(B_8)$ where $S_i(B_i)$ refers to the output of the i-th S box. To repeat, each of the functions S_1, S_2,..., S_8, takes a 6-bit block as input and yields a 4-bit block as output. The table to determine S_1 is shown and explained below: If S_1 is the function defined in this table and B is a block of 6 bits, then $S_1(B)$ is determined as follows: The first and last bits of B represent in base 2 a number in the decimal range 0 to 3 (or binary 00 to 11). Let that number be i. The middle 4 bits of B represent in base 2 a number in the decimal range 0 to 15 (binary 0000 to 1111). Let that number be j. Look up in the table the number in the i- th row and j-th column. It is a number in the range 0 to 15 and is uniquely represented by a 4 bit block. That block is the output $S_1(B)$ of S_1 for the input B. For example, for input block B = 011101 the first bit is "0" and the last bit "1" giving 01 as the row. This is row 1. The middle four bits are "1110". This is the binary equivalent of decimal 13, so the column is column number 13. In row 1, column 13 appears 5. This determines the output; 5 is binary 0011, so that the output is 0101. Hence $S_1(011101)$ = 0011. Example: For the first round, we obtain as the output of the eight S boxes:

41	35	3	43	11	51	19	59	27
49	34	2	42	10	50	18	58	26
57	33	1	41	9	49	17	57	25

$K_1+E(R_0)$=100101010001100001010101010111011010000 10111000111

$S_1(B_1)S_2(B_2)S_3(B_3)S_4(B_4)S_5(B_5)S_6(B_6)S_7(B_7)S_8$=0101110 01000 00101011 010110010111

The final stage in the calculation of f is to do a permutation P of the S-box output to obtain the final value of f: f = $P(S_1(B_1)S_2(B_2)...S_8(B_8))$ P yields a 32-bit output from a 32-bit input by permuting the bits of the input block. Example: From the output of the eight Sboxes: $S_1(B_1)S_2(B_2)S_3(B_3)S_4(B_4)S_5(B_5)S_6(B_6)S_7(B_7)S_8$=0101110 01000 0010101101011001 0111

we get f = 0010 0011010010101010100110111011

$R_1=L_0+f(R_0,K_1)$= 1100110000000000110011001
111 1111+ 00100011010010101010100110111011
= 11101111010010100110010101000100

In the next round, we will have $L_2 = R_1$, which is the block we just calculated, and then we must calculate $R_2 = L_1 + f(R_1, K_2)$, and so on for 4 rounds. At the end of the sixteenth round we have the blocks L_4 and R_4. We then reverse the order of the two blocks into the 64-bit block $R_{16}L_{16}$ and apply a final permutation IP^{-1} as defined by thefollowing table

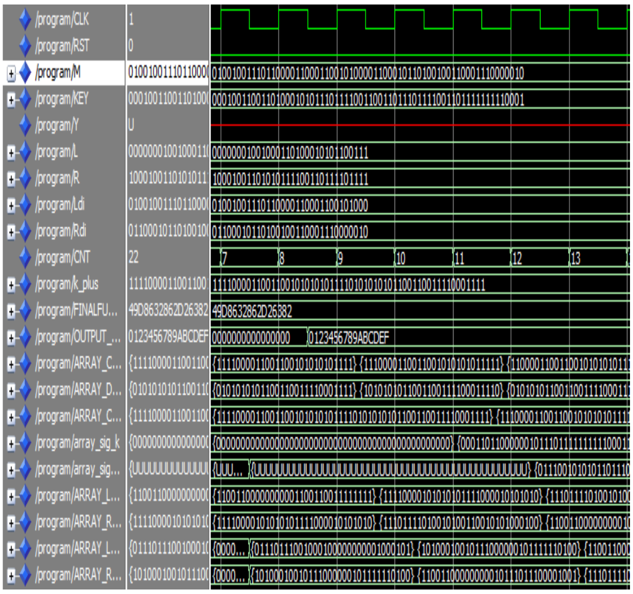

Fig. 3: Output waveform for DES Encryption

:

That is, the output of the algorithm has bit 40 of the pre output block as its first bit, bit 8 as its second bit, and so on, until bit 25 of the pre-output block is the last bit of the output.

Example: If we process all 4 blocks using the method defined previously, we get, on the 4th round,

L_4 = 10100010010111000000101111110100
R_4= 01110111001000100000000001000101

We reverse the order of these two blocks and apply the final permutation to

R_4L_4=
01110111001000100000000001000101101000100
10111000000101111110100

IP^{-1}=010010011101100001100011001010000110001011
0100100110001110000010

this in hexadecimal format is 49D8632862D26382.

This is the encrypted form of

M = 0123456789ABCDEF: namely,

C = 49D8632862D26382.

Decryption is simply the inverse of encryption, following the same steps as above, but reversing the order in which the sub-keys are applied

CGS units, such as current in amperes and magnetic field in oersteds. This often leads to confusion because equations do not balance dimensionally. If you must use mixed units, clearly state the units for each quantity in an equation.

The SI unit for magnetic field strength *H* is A/m. However, if you wish to use units of T, either refer to magnetic flux density *B* or magnetic field strength symbolized as $\mu_0 H$. Use the center dot to separate compound units, e.g., "$A \cdot m^2$."

IV. CONCLUSION

In this paper, the DES algorithm has been analysed using Xilinx tool and implemented on modelsim Spartan 3 kit. Theresults are shown in the form of output waveforms .
